ABSTRACT

Disclosed is a system and method for at least one finite-state process for enabling an automated task flow, said method comprising the steps of: listing of necessary states significant for a data processing; determining data parameters used for designation of necessary states; assembling a data structure and a process (object) corresponding to information about at least one necessary state significant for the process; and running the process involving movement of objects from a node to at least one other node for a perpetual run until a condition with a set of parameters are met by an event.

APPLICATION**

[0001] This application claims priority to U.S. application Ser. No. 15/268,802, “Method of Binding Data and Processes with the Use of Universal Computing Elements”, which claims priority to 62/221,124, filed on Sep. 21, 2015, which is incorporated herein by reference. Furthermore, this application also claims priority to U.S. application Ser. No. 15/077,626, “Universal Computing Element (UCE) and the Mode of Computing with the Use of UCE”, which claims priority to 62/137,079, filed on Mar. 23, 2015.

FIELD OF INVENTION

[0002] The invention pertains generally to the field of digital communications, and more particularly to a node-based network, whereby data and processes are bound using universal computing elements for a conditioned-triggered process until a condition with a set of parameters are met by an event.

BACKGROUND OF INVENTION

[0003] Conventional electronic databases provide limited functionality, especially as advanced network access to data increasingly requires higher speed storage and access, as well as more complex data formats. For example, there is increasing need for providing higher intensity of data flow, instant availability of data storage, support of incompatible data formats, as well as various changes in data processing. Due to growing complexity of data processing, data processing becomes more time-consuming, thus complicating the process of making changes thereto, and requires higher professional skills of developers to build and modify more complex data systems that more flexibly allow organized online interaction between large number of various system applications.

[0004] Conventional computer-implemented design systems provide software tools which often encounter practical problems in software development. They tend to be too long, expensive, inflexible. Additionally, there is a high cost to perform updates, an increasing dependence on the developer—not to mention a whole host of developer problems (e.g., modern programming with implicit selection of status resulting in inherent technical problems, succession/inheritance, etc.). Thus, it would be desirable to address such conventional problems to improve computer programming and software development. There is currently a void in the market for an all-in-one toolkit for non-coders to build a customizable automated task loop that reduces computational load by distributing a logical circuit across nodes, wherein there is a perpetual transfer of objects across said nodes until a state change occurs ending the task loop.

SUMMARY

[0005] The invention automates data processing flow as a set of system states, particularly whereby data and processes are bound using universal computing elements (UCE), as

finite-state automata with explicit selection of states in real-time operation, thus facilitating construction of finite-state automata/processes to users. For example, data flow is processed as a set of system states significant for a given process purpose. Preferably for such purpose, data and processes are provided as finite-state automata automatically with explicit selection of states in real-time operation, thereby enabling automata-based construction of finite-state automata or processes, for example, for users who are not programmers. Advantageously, data processing is organized to reduce impact of inefficient conventional data usage, particularly via data transfer processed innovatively into state format and usage of automata-based programming for data processing.

[0006] It is contemplated generally herein that computer-implemented systems/methods enable computer programming and software development using a node architecture, whereby at least one of a software, computer program, source/object/assembly code, firmware or other reconfigurable logic or signal processing instructions include at least one node. For example, UCE-bound data and processes in a node-configured software program or functionally equivalent reconfigurable hardware may be implemented programmably in general-purpose cloud operating system function according to related or unrelated algorithms, as well as for one and/or more owners, whereby such software runs on server or cloud, (private, public, or hybrid,) and/or hardware via firmware, micro-circuit, board, or equivalent functional logic, in order to achieve construction of finite-state automata/processes to users.

[0007] It is one object of the claimed invention to claim and disclose a system and method for at least one finite-state process for enabling an automated task flow, the system and method comprising the steps of: listing of necessary states significant for a data processing; determining data parameters used for designation of necessary states; assembling a data structure and a process (object) corresponding to information about at least one necessary state significant for the process; and running the process involving movement of objects from one node to at least a second node for a perpetual run until a condition with a set of parameters are met by an event, ending the task loop.

[0008] It is another object of the invention to disclose and claim a system and method for constructing at least one finite-state process for enabling an automated task flow comprising: a list of states significant for a data processing; determination of data parameters used for designation of necessary states; an assembly of a data structure and a process (object) corresponding to information about at least one necessary state significant for the process; and a process run involving movement of objects from one node to at least a second node for a perpetual run until a condition with a set of parameters are met by an event, or at least one of a counter and run-time threshold is met, thereby achieving computational load efficiencies and task-overflow avoidance.

[0009] These and other features and improvements of the present application will become apparent to one of ordinary skill in the art upon review of the following detailed description when taken in conjunction with the several drawings and the appended claims.

BRIEF DESCRIPTION OF FIGURES

[0010] The drawings illustrate the design and utility of embodiments of the present invention, in which similar

elements are referred to by common reference numerals. In order to better appreciate the advantages and objects of the embodiments of the present invention, reference should be made to the accompanying drawings that illustrate these embodiments. However, the drawings depict only some embodiments of the invention, and should not be taken as limiting its scope. With this caveat, embodiments of the invention will be described and explained with additional specificity and detail through the use of the accompanying drawings in which:

[0026] FIG. 11 illustrates a process flow of the nodal configured UCE, in accordance with one or more aspects of the present invention.

[0027] FIG. 12 illustrates a process flow of the nodal configured UCE, in accordance with one or more aspects of the present invention.

[0028] FIG. 13 illustrates an exemplary environment illustrating the extent of interaction between companies employing the node-based finite-state task loop.

DETAILED DESCRIPTION

[0029] The invention automates data processing flow as a set of system states, particularly whereby data and processes are bound using universal computing elements, as finite-state automata with explicit selection of states in real-time operation, thus facilitating construction of finite-state automata/processes to users. For example, data flow is processed as a set of system states significant for a given process purpose. Preferably for such purpose, data and processes are provided as finite-state automata automatically with explicit selection of states in real-time operation, thereby enabling automata-based construction of finite-state automata or processes, for example, for users who are not programmers.

[0030] Generally, it is contemplated herein that computer-automated software method and/or hardware system binds and constructs data and process electronically using universal computing element, whereby data and process associated with a first data processing flow are bound electronically, wherein such data and process are bound using one universal computing element(s) corresponding to system state(s) significant to the data processing flow. Finite-state automata or process may be constructed automatically to facilitate real-time operation of the data processing flow according to such universal computing element(s) via explicit selection of such system state(s). Advantageously, data processing is organized to reduce impact of inefficient conventional data usage, particularly via data transfer processed innovatively into state format and usage of automata-based programming for data processing.

[0031] In accordance with one embodiment of the present invention, data is processed per following automated steps:

[0032] (1) company data (both found in databases and formed in the course of the company activity without storing as the records in databases) is transformed automatically into finite set of states with the use of the Universal Computing Element;

[0033] (2) in the course of data processing in one or more Universal Computing Elements, source data is not sent; instead, parameters required for the processes are sent automatically, and whenever necessary confidential information is replaced automatically by its identifiers;

[0034] (3) automata-based programming by adding of new Universal Computing Elements (automata) is used automatically for data processing; and

[0035] (4) data is exchanged automatically between units “inside” the diagram of the process and between external sources of data, including other units “external” with regard to current process diagram of the units; therefore, flexible and easy integration is provided.

[0036] Thus, users are automatically provided processing environment wherein data converted into more convenient form, whereby such environment provides for processing more efficiently in terms of finite-state automata. Preferably, users cannot process data not in the mode of automata, such that data transferred in this environment is automatically converted into the set of finite states always for generating resulting processes. Furthermore, processes running in this environment may generate new states also in such automata mode. Advantageously, data processing system configured automatically according to such automata-based programming environment provides opportunities for flexible expansion and constructing stable controllable links to integrate with other network computing systems.

[0037] In accordance with one or more aspect of the present invention, one or more Universal Computing Element (UCE or COREZOID) is provided for automatic configuration, as shown schematically in FIG. 1, with one or more of the following structural functions, programmable attributes, or characteristic definitions or nomenclature:

queue—queues of objects in the unit;

semaphores—system and user semaphores; when certain values are reached, semaphore triggers parallel process of escalation;

counters—system and user counters; counter may shows the value only, without action (this is how counters differ from semaphores);

system semaphore T—specified time of the object staying in the unit;

system semaphore N—specified number of objects that can be queued in the unit;

other parameters—which can be specified for objects queued in the unit;

functions—actions to be performed on the object from the queue in the unit; also functions—actions to be performed on the object from the que in the unit; also, functions can be in the form of API, software code, other conveyor etc.; when specified values of semaphores and/or functions are violated (exceeded), escalation is triggered (can be arranged with the use of conveyor as well) accepting the objects for processing;

f—call of relevant function, unit(i);

F—for each unit there is a corresponding function which can be realized through operator, API, code, other unit;

Cm—counter, time T of the oldest object in queue

Cn—number of objects in queue

{Ci}—custom counters

object—set of parameters characterizing the object; according to certain rules, data on the object is processed in the unit—function is applied to the object;

functions—actions to be performed on the object from queue in the unit; functions can be in the form of API, software code, other process etc.;

logic—tools for controlling logic in the unit; system and use logics;

system logic T—specified time of the object staying in the unit;

system logic N—specified number of objects that can be queued in the unit;

[0038] For optimization purposes in large systems, counters may be run or accessed on separate servers in a network.

[0039] In one embodiment of the present invention, CALLBACK logic is used as basic logic element in the Universal Computing Element. For example, CALLBACK may be used for asynchronous interaction with external API and other processes, such as request when gets to the unit with CALLBACK “hands up” and waits for update from external system of other process. Owing to CALLBACK logic, processes created with the use of the Universal Computing Elements can operate in the mode of finite-state automata, as shown in FIG. 2.

[0040] Regarding operation of the Universal Computing Element, generally such unit structurally in hardware, firmware, and/or software embodied using one or more processor, computer, controller, etc., comprises one or more queues, one or more counters, one or more queues, one or more functions from counters (e.g., semaphores), as well as functions applied to queued objects. Initially, information about one or more object may be transferred automatically to the unit queue input (i.e., object identifier—Oi). Such queue may be configured and/or described by standard semaphores and/or counters, e.g., semaphores of time, quantity, etc.

[0041] Moreover, according to pre-determined or modified rules and/or parameters, data on one or more object is processed in the UCE unit, i.e., the function is applied to such object. Application of function to such object preferably has defined limitations on time and quantity. Also, such functions can be realized through API, code, conveyor, operator, etc. After successful processing of object data, the unit delivers results for further processing to other units, or processing is completed. In case of deviation from normal operation of the unit (e.g., processing time exceeded, more objects in queue which are waiting for processing, etc.), the unit triggers escalation (e.g., escalation algorithm may deploy additional units). Escalation parameters and conditions can be extended based on needs of one or more algorithm.

[0042] In particular, one embodiment of present invention includes one or more operational method steps for data transformation automatically, as follows:

[0043] Step 1. Determination of list of system states significant for data processing;

[0044] Step 2. Determination of data parameters used for designation of necessary states;

[0045] Step 3. Development of process algorithm for data processing;

- [0046] Step 4. Designing of Universal Computing Element layout which provides for implementation of the process algorithm;
- [0047] Step 5. Setting of parameters sent to system and between Universal Computing Elements within the diagram, when units with CALLBACK logic are included into parts of process where system should stop waiting for next event significant for the process. Upon occurrence of one of significant events, system may continue processing of information according to basic diagram to next UCE with CALLBACK logic or final UCE according to the diagram, e.g., go to the next state. If the event significant for the system is expiry of specified waiting time, it is possible to use (i.e., instead of CALLBACK logic) the system semaphore T which turns system to next state upon occurrence of the event, i.e. expiry of specified waiting time.
- [0048] Step 6. Sending flow of data to be processed to input of diagram assembled of the Universal Computing Elements.
- [0049] Step 7. Presence of created system of units with CALLBACK logic in the basic diagram leads to mode of data processing, when after each or some significant event, system goes into new significant state and stays in it for a specified time until next significant event occurs.
- [0050] Step 8. Since each Universal Computing Element may process, obtain and transfer data both to internal and external (i.e., with regard to the process diagram) units, movement of the request (e.g., single set of data about the event in the system) from one unit to another according to the process algorithm and diagram may lead to changing a number of states (e.g., copying, modification, etc.) instead of one state, and initiate new processes built on the same principles.
- [0051] In one embodiment regarding automated payment of invoices of individuals for services, one or more bank institution based on contracts with service providers (e.g., utility company, telecommunication company, etc.) may receive database on residents' debts for services of such provider company automatically to arrange acceptance of payments from these individuals. Optionally, such provider bank provides individuals opportunity to find out actual amount of their debt and pay invoice issued by the company by any convenient means automatically, e.g., at the bank branch, ATM, through Internet client-bank system, smartphone application, or any other available means. However, conventional invoice payments by individuals are unreliable, for example, since individuals may need to make a request to the database on the amount of bank debt, and initiate payment knowingly; hence, individuals may forget to pay in time or permanently defer their payments altogether, and as a consequence, cash inflow to service provider is reduced significantly. Additionally, customer may routinely contact bank on other transactions, e.g., deposit, transfer receipt, loan servicing, etc., during which customer may pay invoices, i.e., if such customer considers payment then conveniently.
- [0052] Thus, advantageously according to one or more aspect of the present invention, automated provision of computer-implemented steps facilitates timely receipt of money by service provider and simplifies procedure of individual invoice payment due to more convenient payment procedure, for example, by eliminating necessity to give a request to the bank of the amount of debt. Preferably, automated invoice for payment of debt waits for customer in any channel of bank service. One automated embodiment of preferred provision of computer-implemented steps follows:
- [0053] Step 1. Automatically create finite-state automaton with two system states; define the significant states of the system:
- [0054] (1) Wait for bank customer in whose name invoice is issued at bank point of service, e.g., 30 days, until information on amount of debt is updated;
- [0055] (2) Display and wait for payment of invoice to pay for services within 10 minutes (i.e., maximum time of contact with customer in bank's service channels).
- [0056] Step 2. Define various parameters of data:
- [0057] (1) Information about the service, e.g., type;
- [0058] (2) Identifier of the individual, e.g., Client_id; and
- [0059] (3) Amount of invoice for payment, e.g., amount.
- [0060] Step 3. Develop the process algorithm for data processing, as shown in FIG. 4
- [0061] Step 4. Design Universal Computing Element layout, as shown in FIG. 5.
- [0062] By designing UCE unit layout, for example, system configured automatically such that after receiving data of specific request (i.e., information about debt of certain individual) at any time stay in mode of waiting for significant actions of bank customer automatically in one of the following states:
- [0063] (1) Waiting for bank customer in whose name invoice is issued at bank point of service, e.g., 30 days, until the information on amount of debt is updated; and
- [0064] (2) Waiting for pressing the "Pay" button by customer in response to bank offer to pay executed payment document, e.g., 10 minutes, maximum time of contact with customer in bank' service channel.
- [0065] Optionally, such system configuration is arranged using CALLBACK logic in units 4 and 6 and system semaphore in units 4, 6.
- [0066] Step 5. Setting parameters sent to the system and between Universal Computing Elements within the diagram. Request in the process shall be set of data described in Step 2.
- [0067] Step 6. Sending data flow, e.g., table with data on amount of individual invoices sent to system input, as sequence of requests.
- [0068] Step 7. Passing one or more request through diagram of the process (i.e., automaton units) results in "stopping" of data concerning each transaction in the unit corresponding to current state of the system; upon occurrence of event significant for the process (e.g., appearance of customer in service channel) system automatically goes to next state according to the algorithm and diagram of the process.
- [0069] In another embodiment, data flow is transformed automatically into the automaton comprising three (i.e., instead of merely two) states, adding opportunity for customer to accept or refuse invoice payment, as follows:
- [0070] Step 1. Create finite-state automaton with three system states; define significant states of the system automatically, as follows:

[0071] (1) Waiting for bank customer in whose name invoice is issued at bank point of service, e.g., 30 days, until information on amount of debt is updated;

[0072] (2) Waiting for customer decision in response to bank offer to pay invoice issued to customer, e.g., 10 minutes, average time of customer servicing at bank; and

[0073] (3) Waiting for payment of invoice sent to customer after receiving customer consent to pay, e.g., 10 seconds, maximum period of invoice payment in the bank's service channels.

[0074] Step 2. Define various parameters of data:

[0075] (1) Information about the service, e.g., type;

[0076] (2) Identified individual, e.g., Client_id; and

[0077] (3) Amount of invoice for services, e.g., amount.

[0078] Step 3. Develop the process algorithm for data processing, as shown in FIG. 6.

[0079] Step 4. Designing layout of Universal Computing Elements, as shown in FIG. 7.

[0080] Regarding UCE unit layout design, it is contemplated herein generally to automate creating a system which after receiving data of request (e.g., information about debt of certain individual) at any time stay in mode of waiting for significant actions, for example, of bank customer in one of the following states:

[0081] (1) Waiting for bank customer in whose name the invoice is issued at bank point of service, e.g., 30 days, until information on amount of debt is updated;

[0082] (2) Waiting for customer decision in response to bank offer to pay invoice, e.g., 10 minutes; and

[0083] (3) Waiting for pressing "Pay" button by customer in response to bank offer to pay executed payment document, e.g., 10 seconds.

[0084] Optionally, such system is arranged due to use of CALLBACK logic in units 4, 6 and 9 and system semaphores T in units 4, 6 and 9.

[0085] Step 5. Setting of parameters sent to the system and between Universal Computing Elements within the diagram; request in the process may be the set of data described in Step 2.

[0086] Step 6. Sending of data flow; table with data on amount of individual invoices is sent to system input, as sequence of requests.

[0087] Step 7. Passing of one or more request through the diagram of the process (i.e., automaton units) results in "stopping" of data concerning each transaction in the UCE unit which corresponds to current state of the system; upon occurrence of event significant for the process (e.g., appearance of customer in service channel) the system automatically goes to next state according to the algorithm and diagram of the process.

[0088] Generally, in accordance with one or more aspects of the present invention, it is contemplated that one or more embodiments automate a computer-implemented system and/or method in accordance with one or more of the following structural and/or programmable limitations, featured functionality, or descriptive notes:

[0089] (1) Multi-state automaton examples show various ways of solving system task using Universal Computing Elements, which differ accordingly by parameters of finite-state automaton being created.

[0090] (2) During data flow (e.g., list of debtors with indication of amount of debt) to input of the system,

one or more automaton is processed automatically in one or more significant states, e.g., waiting for customer, for consent to pay, for payment, etc. (i.e., with regard to indebted customer).

[0091] (3) Construction of the system (e.g., automaton with three or two states) is carried out by constructing algorithm for data processing and subsequent implementation of the algorithm in diagram of element binding, comprising Universal Computing Element with one or more functions "active".

[0092] (4) Changing the algorithm of system operation is performed automatically according to change in structure and type of Universal Computing Element functions used.

[0093] (5) Interaction of created system with external systems is performed with use of API and/or CallBack functions (logics).

[0094] (6) Preferable system may be configured automatically in mode of waiting for information from external systems, and changes state upon receiving relevant data.

[0095] (7) Sequence of states hardly coded with the use of the algorithm and diagram automates transforming the data on states into processes which in their turn change state of the system, i.e., "States generate processes, and processes generate states".

[0096] (8) When system stays in mode of waiting for significant event, it results instantly in response of the system (i.e., instant availability of data) to such change.

[0097] (9) System constructed in this automated manner allows processing of data not compatible beyond its limits using API logic. Hence present method of data processing may enhance flexibility and complexity of systems considerably owing to possibility of combining and processing data of unlimited number of applications.

[0098] (10) The proposed method of system development substantially reduces cost of process of making changes into information systems. Changing the system (e.g., addition/removal of units, logics inclusion to/exclusion from a small set, connection/disconnection of links to external system addresses, etc.) may not require specialized programming skills.

[0099] FIG. 1 illustrates Universal Computing Element (UCE or COREZOID) structure schematically. FIG. 2 illustrates process assembly of Universal Computing Element (UCE or COREZOID) schematically showing steps to transform data into information about states using system assembled with UCE/COREZOID. FIG. 3 illustrates binding data structures and information about states schematically. For example, a set of customer historical data is shown to be collected electronically by a bank, and history of customer transactions is transformed automatically onto set of states significant for bank process flow, using data processing system assembled using Universal Computing Elements (UCE/COREZOID). As soon as the process, for which one state or several states are determined to be significant, appears at the bank, the system preferably changes state to next one, according to present process algorithm. FIG. 3 example shows lawyer, a man of 47 years old, having deposit and active credit card; owing to partner program between bank and Tesla car manufacturer, bank automatically makes special offer on buying the car of Tesla model-S on credit to all customers—lawyers at age of 47

years. At the time when the process of the offer sending is initiated, the system automatically determines compliance of the candidate with specified terms and creates new state in the system—"sending of Tesla model-S buying on credit" to the customer ID 8234. Situation when the promotional event started in the past, but the customer reaches the age of 47 years now, gives the same result (i.e., adding of a new state); thus changing "age" state results in change of "Tesla model-S offer" state.

[0100] FIG. 4 illustrates invoice-payment algorithm of one method flow chart automated steps of solving task set an example by creating finite-state automaton with two states. FIGS. 5a-5c method flow chart illustrate an invoice payment process diagram schematically with layout of the Universal Computing Element system automated steps, which allow solving the task set in the example by creating the finite-state automaton with two states according to the algorithm stated above. As shown, bidirectional arrows define bidirectional data communication between created system of Universal Computing Elements with external systems by means of API application programs. According to working protocol, one or more parameters contained in request (e.g., type, Client_id, amount) sent from the system, and in response data on results of processing (e.g., customer or not, what button is pressed by the customer in the interface, etc.) is received. Moreover, as shown, unidirectional arrow defines unidirectional data communication between created system of Universal Computing Elements with external systems and/or other processes, assembled of Universal Computing Elements, for example, by using CallBack function. According to protocol of CallBack function, for example, request "hangs up" in Universal Computing Element, and waits for update from external system or other process.

[0101] FIG. 6 illustrates invoice payment process algorithm flow chart of one method of automated steps solving the task set in the example by creating the finite-state automaton with three states. FIGS. 7a-7d illustrate schematically a method flow chart layout of the Universal Computing Element system automated steps, which allows solving the task set in the example by creating the finite-state automaton with three states according to the algorithm stated above.

[0102] Now in reference to FIG. 8. FIG. 8 illustrates an exemplary schematic of the Universal Computing Element (UCE) structure in a node configuration, according to one or more aspects of the present invention. The node configuration of the UCE in a network of nodes is a significant improvement of the automated task flow by enabling perpetual shuttling of objects from a node to at least another node. This perpetual shuttling persists until at least one of a condition with a set of parameters is met by the event or a counter/time limit is met. In the instance the event obligation is met and satisfied, the task is executed as prescribed. In the event at least one of counter limit or time limit is met, the task loop is terminated, thereby ending the process-run. As a result, this node configuration of the UCE and the novel process-run features enable a number of computer processing efficiencies, namely better distributing computational load throughout nodes in a network and avoiding a task-queue overflow.

[0103] As shown in FIG. 8, such a node configuration of the UCE, in general terms, is structurally in hardware, firmware, and/or software embodied using one or more processor, computer, controller, etc., and comprises one or

more queues, one or more counters, one or more functions from counters (e.g., semaphores), as well as functions applied to queued objects. Initially, information about one or more object may be transferred automatically to the unit queue input (i.e., object identifier—Oi). Such queue may be configured and/or described by standard semaphores and/or counters, e.g., semaphores of time, quantity, etc.

[0104] Moreover, according to pre-determined or modified rules and/or parameters, data on one or more object is processed in the UCE unit, i.e., the function is applied to such object. Application of function to such object preferably has defined limitations on time and quantity. Also, such functions can be realized through API, code, conveyor, operator, etc. After successful processing of object data, the unit delivers results for further processing to other units, or processing is completed. In case of deviation from normal operation of the unit (e.g., processing time exceeded, more objects in queue which are waiting for processing, etc.), the unit triggers escalation (e.g., escalation algorithm may deploy additional units). Escalation parameters and conditions can be extended based on needs of one or more algorithm. The UCE in node configuration comprise structural functions and programmable attributes with the same characteristic definitions and nomenclature as described earlier in the FIG. 1 description.

[0105] While not shown in FIG. 8, in a preferred embodiment, a system and method for creating a finite state automation using a nodal UCE may comprise a listing of necessary states significant for a data processing; determining data parameters used for designation of necessary states; assembling a data structure and a process (object) corresponding to information about at least one necessary state significant for the process; and running the process involving movement of objects from a node to at least one other node for a perpetual run until a condition with a set of parameters are met by an event.

[0106] While in other embodiments, also not shown, after assembling a data structure and a process (object) corresponding to information about at least one necessary state significant for the process; objects are in a perpetual transfer from a node to at least one other node until at least one of two things occur: The condition with a set of parameters are met by an event or prior to the condition being met, a pre-defined threshold of a counter limit or time limit is reached, terminating the process run (task loop).

[0107] Alternatively, the task loop may end prior to the condition being met solely upon the counter limit being reached. In another alternative embodiment, the task loop may end prior to the condition being met solely upon the time limit being reached. In yet other alternative embodiments, the task loop may end prior to the condition being met only upon both the counter limit and time limit are reached. Such task loop termination features are intended to avoid a task-queue overflow in a finite-state automation process.

[0108] A business process is the most general usage case of the node-based automation platform being described. Generally speaking, a business process is a partially ordered set of tasks aimed at achieving a specific purpose (production of goods, rendering of a service, etc.). In this case, the actions imply simple calculations and conversion of data portions (or records in terms of traditional database management systems), which are in this context called objects. In itself, the automation platform with smart nodes allows to

manipulate objects, calculate their number, sum up numerical values in the objects, and so on. In some simple, but nevertheless, important cases, such as regarding many financial business processes, this proves already sufficient. However, the scope of the smart node platform is not restricted to this, as one of the most important tools of the platform is its free interaction with any external applications through the API (application programming interface).

[0109] In a preferred embodiment, the processes represent a certain finite number of positions and transitions presented in the form of a set of nodes interconnected with arcs. The arcs define the relationship and sequence of a process. The process is carried out by movement of objects from input positions (nodes) to output positions due to reaction to events, which can come either from external systems (interaction with API) or performance of functions in the nodes during process execution. Alternatively, other signifiers (dotted line, arrow, etc.) may be used to signify the relationship and sequence of a process via the user interface. The user interface may also give a user the option to produce a change of its own processes through an API. This allows implementing not only simple Petri nets, but also adaptive ones, i.e. able to modify the net so as to adapt to processing of new events not previously considered in the system architecture.

[0110] While not shown in the schematic of a single node in FIG. 8, the node determines what should be done to an object by means of a linearly ordered set of functions. The nodes can be of four types: starting node, execute node, and final node. In some embodiments, each of the three types of nodes may have subset of nodes, each with a unique structural, functional, or programmable attribute. The starting node is always one for a process and is used to specify the node actually to be the first to be run, as well as serves as a reference point for process debugging and tracing. Similar to the starting node, the final node performs no action, while only recording the fact of an object processing completion in the node. Alternatively, object processing may not require a final node—just a start node and execute node—with object processing information stored in a conventional memory element or remote server. The execute node may further comprise a normal node and an escalation node, which are semantically equivalent. Their differences are relative and introduced for descriptive reasons: these nodes are suggested to be marked with different colors in the user interface. It is thereby assumed that the process developer uses normal nodes to describe the ‘normal’ course of the process, while using escalation nodes to describe the response to exceptional conditions.

[0111] The execute node executes the task upon the condition with the set of parameters are met by the event. In some embodiments, the execute node terminates a task loop

upon an expiration of a pre-defined amount of time the process has been running. In this embodiment, the object perpetually transfers from a node to at least one other node until at least one of an event obligation is satisfied and a counter or time threshold is reached.

[0112] Every process run requires a function or command. Each function has a tag, or a name that defines the executable command, as well as a set of parameters specific to the command. Functions in the node are ordered and executed in the order they have been recorded, with two functions—Function Counter limit and function Time limit—having priority and being executed first if present in the node and the conditions for their execution are met. These two functions allow you to avoid task queue overflow and avoid infinite hang-up of tasks in the nodes. The Process run is the actual implementation of a business process. Any process has a starting point and an end point, but there also may be permanent processes. Any process can undergo any number of runs, including those initiated in parallel. process run is performed by the node instances. The course of a process can be monitored and traced using indicators (or dashboards).

[0113] An indicator is a means for observing and monitoring progress of a process. The following indicators are provided to show the statistics for the period and/or the instantaneous value in real time: The number of tasks incoming to the node; the number of tasks outgoing from the node; the total number of consumed clock cycles; the number of consumed clock cycles selected by the process.

[0114] A node instance is a software object having ‘free will’. Each node instance is associated with a queue of objects to be processed. Node instances operate independently and asynchronously, as there is no ‘supervisor’ over them. Synchronization and interaction between node instances occur due to exchange of objects. Each node instance selects the next object from its queue, executes the prescribed functions that may have a spin-off, and subsequently sends the object for processing to another instance’s queue, and then immediately proceeds to processing the next object. Thus, nodes form a chain that processes the incoming sequence of objects at the maximum possible productivity ratio.

[0115] An object implies passive data structure used to store and transfer information from one processing node instance to another during runtime. Each object is a set of named parameters. A parameter has a name and value, and the value can be both simple type and a nested task with its own parameters and values. Thus, the task is a hierarchical associative memory of “key-value” type.

[0116] Now in reference to FIG. 9, which illustrates the various functions of the nodal configured UCE, according to one or more aspects of the present invention. The various functions are further defined in the below table.

Name	Description
Task Counter (Alert when there is task a queue)	If the time of the object presence in the node exceeds the maximum time, the object is transferred to the target node
Time limit (Limit the time of the task in the node)	The object is unconditionally transferred to the target node. It is the last command of the processing program
Go	The condition is a conjunction in terms of comparing values of parameters of objects with the constants. If the condition is met, the object is transferred to the target node

-continued

Name	Description
Condition	Synchronous call of an external API method in JSON, XML, SOAP formats. The object remains in the node while the API method is being executed.
API Call	Synchronizing with an external process. The object remains in the node, until a response from the external process arrives
Waiting for callback	Specified language (JavaScript or Erlang) code fragment is interpreted. Accesses the object parameters via the variable data.
Code	The object may be partially copied to the starting node of another process
Copy task	The object may be partially copied to the starting node of another process, thus causing processing of this object by another process. Once processing is complete, the called object must return the processed object by command RPC_REPLY.
Modify task	The object is returned to the calling process. The process ID is stored in the node.
Call process	Values of certain parameters are summed up
Reply to process	A value is set to the object parameter.
Sum	The current object is transferred to the local queue.
Set parameter	process name, node name

[0117] FIG. 10 illustrates a process flow of the nodal configured UCE, in accordance with one or more aspects of the present invention. More specifically, the point of input accepts text command messages and synthesizes it into executable workflow based on the following steps: Create a new process; define the list of nodes that need to be created; create the nodes from the list; define the code that needs to be added to the node with the execution command; add code logic to the nodes with command; define transitional conditions between the nodes; and add “if” or “go” logic to the nodes.

[0118] FIG. 11 also illustrates an exemplary process flow of the nodal configured UCE. More specifically, FIG. 11 typifies a parallel customer call and incoming call queue process. The example shows the processing of customer calls to a store and the parallel handling of said calls by said store operations. The general scheme of the business process employing the nodal configured UCE is shown in the flowchart on FIG. 11. Shown is a pathway of at least a start node and at least one other node; the at least one node comprising at least a condition function with a set of parameters. In the example of FIG. 11, the condition defined is for a call from a customer to get through to a store operator and the parallel condition is defined as the receipt of the customer call. The object is any data structure capable of storing and transferring information (pertaining to condition name, value, state, etc.) from the start node to the at least one other node; and execute a process run involving movement of queued objects from a start node to at least one other node for a perpetual run until the condition function with a set of parameters are met by an event (customer call received by the store operator). In other embodiments, the process run may end prior to the condition function being met if at least one of a counter limit is met and a time-limit is met in order to avoid the task-queue overflow in the automation process.

[0119] FIG. 12 describes interaction of buyers and suppliers in terms of purchase and delivery of goods. The purchase process is initiated by the buyer who places the order. The object ‘order’ arising on the buyer’s side is transferred to the supplier using the Copy task function. The process called does not have to ‘know’ anything special about the calling process as all the necessary information is available in the object transferred. In other words, the interaction between the processes is performed by means of data rather than by

management, thus rendering the processes as independent as possible. Further, the supplier’s process after a while responds to the incoming order by means of an invoice. The buyer’s process is waiting for the invoice to arrive. This is ensured by the Waiting for call-back function. If the response (invoice) is not received within a certain time with the time set on the buyer’s side, the purchase process will fail. Thus, although there is no common synchronized ‘supervisor’ of process interaction, no process will get stuck for an infinite period of time.

[0120] If everything goes correctly and the invoice arrives on time, this is confirmed by modification of the original order on the buyer’s side. This means that the invoice is created not as an object separate from the order but is inherently linked to the specific order. Thus, the process allows to automatically eliminate errors such as ‘order number confused’ and ‘this is some other buyer’s invoice’. Note that here the case is taken into account where the supplier can refuse to complete the order for their own reasons (for this purpose it is sufficient for the supplier to set the parameter order=false in the order). Further, payment for the goods is made in a perfectly symmetrical manner, with the supplier now acting as a waiting party. The payment order is also created not as a separate object, but as one associated with the original order, which dramatically reduces the probability of errors and fraud. The same pattern is used for interaction in terms of supplying goods, after which the process ends at the same point where it had started, and the object ‘order’ completes its life cycle.

[0121] FIG. 13 illustrates an exemplary environment illustrating the extent of interaction between companies employing the node-based finite-state task loop. The key advantage of this embodiment is that companies may communicate with any number of companies using a standard protocol, without the need of an API. The limitations of the API are that there are disparate formats making communication complex.

[0122] Communication and the extent of interaction may encompass at least one of the following interactions: peer-to-peer connection; peer-to-peer connection with algorithm hosting with a marketplace; peer-to-peer connection with algorithm hosting and process hosting; algorithm hosting without peer-to-peer connection; process hosting without

peer-to-peer hosting; and finally, algorithm and process hosting without peer-to-peer interaction.

[0123] In a preferred embodiment, process hosting 5-6, 6-7 links access to the process in a marketplace by companies with established limits. Algorithm hosting 2-3, 3-4 loads the algorithm into a marketplace with the setting of limits to use the algorithm.

[0124] Third parties may copy the process to its local companies with the established limits. These third parties are companies that use the resources of at least one of the companies with the established limits, but do not own the resources. The companies, in contrast, with allocated resources have direct access to the marketplace (algorithms and process). In some embodiments, the companies have direct access to the marketplace and with at least one other company with established limits. As a result, communication (data exchange in terms of nodal-based object transfer) may be achieved using a standardized and format-agnostic protocol (contrasting the conventional API-exchanged data). Alternatively, communication or transfer of data may be achieved by an API interface. In alternative embodiments, the object transfer or data transfer may be achieved without the above mentioned perpetual node configured network, but rather through a stage-to-stage manner after a state transfer or change.

[0125] The marketplace is a resource with a catalog of voluntarily published limited and, or publicly available resources of companies (algorithms and processes). As noted earlier, the process is the perpetual transfer of objects from one node to another until an event satisfies an event obligation, or upon a pre-defined counter time or limit is reached—avoiding a task queue overflow. Visually, the process is depicted as a graph where vertices are nodes connected by oriented hedges. The goal, of course, being the execution of the implemented graph with an avoidance of task—queue overflow. The algorithm is an instance of the process published in the marketplace, which third parties can copy for further modification and launch of the node-based finite-state task loop.

[0126] Alternatively, there may not be a single resource or module cataloguing the algorithms, processes, and other voluntarily published or publicly available resources (marketplace), and rather, each of this data or assets may operate in distinct and independent modules or resources for access by companies or third-parties.

[0127] Embodiments are described at least in part herein with reference to flowchart illustrations and/or block diagrams of methods, systems, and computer program products and data structures according to embodiments of the disclosure. It will be understood that each block of the illustrations, and combinations of blocks, can be implemented by computer program instructions. These computer program instructions may be provided to a processor of a general-purpose computer, special purpose computer, or other programmable data processing apparatus to produce a machine such that the instructions, which execute via the processor of the computer or other programmable data processing apparatus, create means for implementing the functions/acts specified in the block or blocks.

[0128] These computer program instructions may also be stored in a computer-readable memory that can direct a computer or other programmable data processing apparatus to function in a particular manner such that the instructions stored in the computer-readable memory produce an article

of manufacture including instruction means which implement the function/act specified in the block or blocks. The computer program instructions may also be loaded onto a computer or other programmable data processing apparatus to cause a series of operational steps to be performed on the computer or other programmable apparatus, to produce a computer implemented process such that, the instructions which execute on the computer or other programmable apparatus provide steps for implementing the functions/acts specified in the block or blocks. In general, the word “node” as used herein, refers to logic embodied in hardware or firmware, or to a collection of software instructions, written in a programming language, such as, Java, C, Erlang, etc. One or more software instructions in the unit may be embedded in firmware. The nodes described herein may be implemented as either software and/or hardware modules and may be stored in any type of non-transitory computer-readable medium or other non-transitory storage elements. Some non-limiting examples of non-transitory computer-readable media include CDs, DVDs, BLU-RAY, flash memory, mobile device, remote device, and hard disk drives.

[0129] Foregoing descriptions of specific embodiments of the invention have been presented for purposes of illustration and description. They are not intended to be exhaustive or to limit the invention to the precise forms disclosed. Modifications and variations are possible in light of the above teaching. The embodiments were chosen and described in order to explain the principles and the application of the invention, thereby enabling others skilled in the art to utilize the invention in its various embodiments and modifications according to the particular purpose contemplated. The scope of the invention is intended to be defined by the claims appended hereto and their equivalents.

I/We claim:

1. A method for at least one finite-state process for enabling an automated task flow, said method comprising the steps of:

listing of necessary states significant for a data processing;

determining data parameters used for designation of necessary states;

assembling a data structure and a process (object) corresponding to information about at least one necessary state significant for the process; and

running the process involving movement of objects from a node to at least one other node for a perpetual run until a condition with a set of parameters are met by an event.

2. The method of claim 1, wherein the node comprises at least one of a start node, execute node, and a final node.

3. The method of claim 2, wherein the execute node executes the task upon the condition with the set of parameters are met by the event.

4. The method of claim 2, wherein the execute node terminates a task loop upon an expiration of a pre-defined amount of time the process has been running.

5. The method of claim 1, wherein each of the any nodes comprise a queue, counter, and at least one function applied to the object.

6. The method of claim 5, wherein the any node comprises at least one of a unique function, counter, and queue.

7. The method of claim 1, wherein the object perpetually transfers from a node to at least one other node until at least one of an event obligation is satisfied and a counter or time threshold is reached.

8. The method of claim 1, wherein each node is associated with a function executed manually via at least one of an API, a code, or another node.

9. The method of claim 1, wherein each node comprises at least a counter time (Ct) measuring time of the oldest object in the queue.

10. The method of claim 1, wherein each node comprises at least a counter number (Cn) measuring a number of objects in the queue.

11. The method of claim 1, further comprising an indicator for monitoring progress of a process.

12. The method of claim 1, wherein a state stay occurs only for a pre-defined time ending a task loop.

13. The method of claim 1, wherein a state stay occurs until a state change is initiated by a triggering event ending a task loop.

14. A method for constructing at least one finite-state process for enabling an automated task flow, said method comprising the steps of:

listing of states significant for a data processing;

determining data parameters used for designation of necessary states;

assembling a data structure and a process (object) corresponding to information about at least one necessary state significant for the process;

running the process involving movement of objects from a node to at least one other node for a perpetual run until a condition with a set of parameters are met by an event; and

terminating the process run prior to the condition being met if at least one of a counter limit is met and a time-limit is met in order to avoid the task-queue overflow in the automation process.

15. The method of claim 14, wherein the node comprises at least one of a start node, execute node, and a final node.

16. The method of claim 15, wherein the execute node executes the task upon the condition with the set of parameters are met by the event.

17. The method of claim 15, wherein the execute node terminates a task loop upon an expiration of a pre-defined amount of time the process has been running.

18. The method of claim 14, wherein each of the any nodes comprise a queue, counter, and at least one function applied to the object.

19. The method of claim 18, wherein the any node comprises at least one of a unique function, counter, and queue.

20. The method of claim 14, wherein the object perpetually transfers from a node to at least one other node until at least one of an event obligation is satisfied and a counter or time threshold is reached.

21. The method of claim 14, wherein each node is associated with a function executed manually via at least one of an API, a code, or another node.

22. A system for constructing at least one finite-state process for enabling an automated task flow comprising:

a list of states significant for a data processing;
determination of data parameters used for designation of necessary states;

an assembly of a data structure and a process (object) constructed corresponding to information about at least one necessary state significant for the process; and
a process run involving movement of queued objects from a node to at least one other node for a perpetual run until a condition with a set of parameters are met by an event.

23. A system for constructing at least one finite-state process for enabling an automated task flow comprising:

a list of states significant for a data processing;
determination of data parameters used for designation of necessary states;

an assembly of a data structure and a process (object) constructed using a Universal Computing Element (UCE) corresponding to information about at least one necessary state significant for the process;

a process run involving movement of objects from a node to at least one other node for a perpetual run until a condition with a set of parameters are met by an event; and

end the process run prior to the condition being met if at least one of a counter limit is met and a time-limit is met in order to avoid a task-queue overflow in the automated task flow.

24. A system for constructing at least one finite-state process for enabling an automated task flow comprising:

a pathway of at least a start node and at least one other node;

the at least one node comprising at least a condition function with a set of parameters;

an object, wherein the object is any data structure capable of storing and transferring information from the start node to the at least one other node; and

execute a process run involving movement of queued objects from a start node to at least one other node for a perpetual run until the condition function with a set of parameters are met by an event.

25. A system to avoid a task-queue overflow in an automation process comprising:

a pathway of at least a start node and at least one execute node;

the at least one execute node comprising at least a condition function with a set of parameters;

an object, wherein the object is any data structure capable of storing and transferring information from the start node to the at least one execute node;

execute a process run involving movement of queued objects from a start node to at least one execute node for a perpetual run until the condition function with a set of parameters are met by an event; and

end the process run prior to the condition function being met if at least one of a counter limit is met and a time-limit is met in order to avoid the task-queue overflow in the automation process.
